1. Introduction

The increasing demand for mobile communication capacity in limited RF spectrum motivates the need for new techniques to improve spectrum utilization. One approach for increasing spectrum efficiency in digital cellular is the use of spread spectrum code division multiple access (CDMA) technology. Another approach is by using the adaptive antenna array in a CDMA system [4] [5], the amount of co-channel interference from users within the same cell as well as neighboring cells can be reduced, and therefore the system capacity can be increased. There exist many adaptive algorithms that must have the ability to separate and extract each user’s signal simultaneously.

In this paper, we investigate the performance of two different blind adaptive array algorithms. The first one is least-squares despread respread multitarget array (LSDRMA) [1] [2] [3], which utilizes the information of the spreading signals of different users in a CDMA system to adapt the weight vectors of a multitarget beamformer. The second one is least-squares despread respread multitarget constant modulus algorithm (LSDRMCMA) [1] [2] [3], which combines the information of the spreading signal and the constant modulus property of the transmitted signal in the adaptation of the weight vectors. The performance test assume that the channel has additive white gaussian noise (AWGN). In section 2, we describe the signal model. Section 3 presents the multitarget adaptive array algorithms, and their derivation. In section 4, we present the simulation results of the different algorithms. Finally, section 5 presents the conclusions.

2. Signal Model

A block diagram of a multitarget adaptive beamformer with \( M \) antenna elements and \( Q \) output ports is shown in fig. 1. The \( M \) antenna elements are assumed to be equally spaced along a line with interelement spacing \( d \), i.e., the array is a uniform linear array. Suppose there are \( q \) signals \( s_1(t), \ldots, s_q(t) \), all centered around a known frequency, say \( f_c \), each impinging on the array with a direction of arrival (DOA) of \( \theta_i, i = 1, 2, \ldots, q \), which is measured clockwise from the broadside of the array. The complex envelope representation of the \( M \times 1 \) array input data vector \( x(t) = [x_1(t), \ldots, x_M(t)]^T \) may be modeled as

\[
x(t) = A(\Theta)s(t) + n(t)
\]

where \( s(t) = [s_1(t), \ldots, s_q(t)]^T \) is the complex envelope representation of the \( q \times 1 \) source vector, \( n(t) = [n_1(t), \ldots, n_Q(t)]^T \) is an \( M \times 1 \) additive noise vector, and \( A(\Theta) = [a(\theta_1), \ldots, a(\theta_q)] \) is the array response matrix with the steering vector \( a(\theta) \) as its \( i \)th column. For a direct sequence CDMA (DS-CDMA) system with \( p \) co-channel users, the impinging signal \( s_i(t) \) from the \( i \)th path of the \( i \)th user may be expressed as

\[
s_i(t) = \sqrt{2P_{di}} b_i(t-\tau_{i0}) c_i(t-\tau_{i0}) \exp[-j\phi_i] \quad i = 1, \ldots, p, \quad l = 1, \ldots, L_{Mi}
\]

where \( L_{Mi} \) is the maximum number of distinguishable multipath components of the \( i \)th user, and \( P_{di}, b_i(t), c_i(t), \tau_{i0}, \text{and} \phi_i \) are the power, the data signal, the spreading signal (PN sequence), the time delay, and the random phase of the signal from the \( l \)th path of the \( i \)th user, respectively. The data signal \( b_i(t) \) and the spreading signal \( c_i(t) \) are given by

\[
b_i(t) = \sum_{n=-\infty}^{\infty} b_{in} \Psi(t-nT_b), \quad c_i(t) = \sum_{m=-\infty}^{\infty} c_{im} \Psi(t-mT_c)
\]

where \( b_{in} \in \{-1, +1\} \) is the \( n \)th data bit of \( i \)th user, \( \Psi(t-nT_b) \) is a unit rectangular pulse of bit period duration \( T_b \), \( c_{im} \in \{-1, +1\} \) is the \( m \)th chip of \( i \)th user, and \( \Psi(t-mT_c) \) is a unit rectangular pulse of chip
period duration $T_c$. In fig. 1, the output signal of the $i$th port is $y_i(k) = \mathbf{w}_i^H(k) \mathbf{x}(k)$, where $\mathbf{w}_i(k) = [w_{i1}(k), \ldots, w_{iM}(k)]^T$ is the adaptive weight vector adjusted by the adaptive control processor using a multitarget-type algorithm.

Fig. 1 The structure of a Multitarget Adaptive Beamformer with $M$ Antenna Elements and $Q$ Output Ports

3. Multitarget Adaptive Array Algorithms

A. Least-Squares Despread Respread Multitarget Constant Modulus Algorithm (LSDRMTCMA)

Here we propose the LSDRMTCMA algorithm [1]. In the base station of a CDMA system, the spreading signals of all users are previously known. So to detect the data bit of $i$th user, the received signal $y_i(t)$ in fig. 2 is correlated with the time delayed spreading signal of $i$th user, $c_i(t - \tau_i)$, where $\tau_i$ is previously known and the correlation output is sent to the detector, which makes a decision based on the correlation output. If the $n$th data bit of the $i$th user is detected correctly by the detector, i.e., $\hat{\theta}_{in} = \theta_{in}$, where $\hat{\theta}_{in}$ is the detector output, the waveform of the $i$th user’s transmitted signal during time period $[(n-1)T_b, nT_b]$ can be obtained by respreading the detected data bit, $\hat{\theta}_{in}$, with the PN sequence of the $i$th user, $c_i(t)$. This respread signal can then be used in the beamformer to adapt the weight vector for $i$th user. The adaptive algorithm that uses this despread and respread technique is referred to LSDRMTCMA algorithm. Fig. 2 shows the block diagram of the LSDRMTCMA for $i$th user. In fig. 2, $r_i(t)$ is given by

$$r_i(t) = a_{PN}r_{PN}(t) + a_{CM}r_{CM}(t)$$ (4)

where

$$r_{PN}(t) = \hat{b}_{in}c_i(t - \tau_i) \quad \text{for} \quad (n-1)T_b < t < nT_b$$ (5)

is the time delayed version of the respread signal of $i$th user, and

$$r_{CM}(t) = \frac{y_i(t)}{|y_i(t)|}$$ (6)

is the complex-limited output of $i$th user, and $a_{PN}$ and $a_{CM}$ are real positive weight coefficients for the respread signal and the complex-limited output of $i$th user, respectively. The coefficients $a_{PN}$ and $a_{CM}$ should satisfy the condition:

$$a_{PN} + a_{CM} = 1, \quad a_{PN}, a_{CM} > 0$$ (7)

Let $y_j(k)$ and $r_j(k)$ denote the $k$th sample of $y_j(t)$ and $r_j(t)$, respectively, in a digital system. The LSDRMTCMA tries to adapt the weight vector $\mathbf{w}_i$ to minimize the cost function

$$F(\mathbf{w}_i) = \sum_{k=1}^{K}|y_i(k) - r_i(k)|^2, \quad F(\mathbf{w}_i) = \sum_{k=1}^{K}\mathbf{w}_i^H\mathbf{x}(k) - r_i(k)^2$$ (8)

where $K$ is the data block size and is set equal to the number of samples in one bit period. Using the extension of Gauss’ method, we obtain the equations for LSDRMTCMA for the $i$th user.
\[ y_i(t) = \left[ w_{i}^H(t) x(t) \right]^T, \quad y_i(t) = \left[ y_i(1+IK), y_i(2+IK), \ldots, y_i((1+IK)) \right]^T \]  

\[ \hat{b}_i = \text{sgn} \left\{ \Re \left[ \sum_{k=1}^{IK} y_i(k) c_i(k - k_{\tau_i}) \right] \right\} \]  

\[ r_{iPN}(t) = \hat{b}_i \left[ c_i(1+IK - k_{\tau_i}), c_i(2+IK - k_{\tau_i}), \ldots, c_i((1+IK) - k_{\tau_i}) \right]^T \]  

\[ r_{iCM}(t) = \left[ \frac{y_i(1+IK)}{y_i(1+IK)}, \frac{y_i(2+IK)}{y_i(1+IK)}, \ldots, \frac{y_i((1+IK))}{y_i((1+IK))} \right]^T \]  

\[ r_i(t) = a_{PN} r_{iPN}(t) + a_{CM} r_{iCM}(t) \]  

\[ y_i(t + 1) = \left[ x(t) x^H(t) \right]^{-1} x(t) r_i^*(t) \]  

where \( c_i(k) \) is the \( i \)th sample of the spreading signal of \( i \)th user, \( k_s \) is the number of samples corresponding to \( \tau_i \) the delay of \( i \)th user, \( \hat{b}_i \) is the estimate of \( i \)th bit of \( i \)th user, and \( r_i(t) \) is the estimated vector of the signal waveform of \( i \)th user over the \( i \)th bit period. The choice of \( a_{PN} \) and \( a_{CM} \) can affect the resulting beam pattern and thus the performance of the system.

**B. Least-Squares Despread Respread Multitarget Array (LSDRMTA)**

The derivation of the LSDRMTA [1] is got if we set \( a_{CM} \) in equation (13) to zero, so the LSDRMTA becomes the LSDRMTA, therefore the LSDRMTA can be viewed as a special case of the LSDRMTA. Fig. 3 shows the block diagram of the LSDRMTA for \( i \)th user.

**4. Simulation Results and Discussion**

In this section we compare the performance of the two algorithms, LSDRMTA, and LSDRMTA under using AWGN channel [2].

**A. Description of System Parameters**

For comparison purposes, we consider a DS-CDMA system with a processing gain, \( N \), equal to 31. The modulation scheme used in the system is binary phase shift keying (BPSK), the carrier frequency \( f_c \) is 1800 MHz, and the data bit rate \( R_b \) is 10 kbps. An 8-element uniform linear array with half wavelength spacing between the elements is assumed to be located at the base station. The number of ports \( Q \) is 8. The sampling rate is four times the chip rate. The \( E_b/N_0 \) for all users is set to 10 dB. The ratio of coefficients \( a_{PN}/a_{CM} \) is 2:1. The DOA of the signals is set to \{ -40°, -30°, -20°, -10°, 10°, 20°, 30°, 40° \} for user number one, user number 2, …, and user number 8, respectively.

**B. Simulation Results in AWGN Channel**

In the AWGN channel case, we assume perfect power control in the base station, so all the signals impinging on the array have the same power level. In fig. 4, we show the performance behavior of all ports in case of LSDRMTA and LSDRMTA algorithms using dynamic data block, which means \( K \) is varied each bit period. We found that the performance is the same approximately for...
the two algorithms. The performance behavior of all ports attenuated to zero dB level, which means that the used spreading signal (PN sequence) satisfy a low cross correlation so all other users are nulled out and remain only the auto correlated user. In fig. 5, we show the directional pattern of port #4 in case of LSDRMTA and LSDRMTCMA algorithms using dynamic data block. The port is assigned to a certain user (for user incident at -10°) and accordingly a peak occurs in the direction of arrival of that user’s signal, but nulls occur in the direction of arrival of all other users’ signals.

5. Conclusions

It is known that, The processing structure of LSDRMTA algorithm utilizes the information of the spreading signals of different users in a CDMA system to adapt the weight vectors of a multitarget beamformer, but the processing structure of LSDRMTCMA combines the information of the spreading signal and the constant modulus property of the transmitted signal in the adaptation of the weight vectors. Then from the simulation and the processing structure, it is clear that the information of the spreading signals is strong enough to extract a user from multiuser system.
